NCX	$\text{Na}^+/\text{Ca}^{2+}$ exchanger
SR	sarcoplasmic reticulum
SERCA	SR Ca^{2+} influx channel
ECC	excitation-contraction coupling
NF	non-failing heart
F	failing heart
AM	actomyosin complex

1 Introduction

The number of known molecular of cardiac excitation-contraction coupling (ECC) mechanisms is enormous and is still growing. It has become impossible to intuitively assess the relative contribution of an individual arrangement in physiological and pathophysiological events. However, such understanding is essential for identifying strategies for treating various types of heart failure. Mathematical modeling and simulation offers a way of handling such an extensive set of data, while still allowing for a (semi)quantitative study. Of course, there are limitations to such an approach, mainly: the accuracy of the model, its complexity (always drastically lower than in reality), low availability of consistent experimental input data, etc. However, calculations and simulations have been already proven to be useful in biological research. As an example, let us mention the correct of Na-K exchanger stoichiometry 3:1, based on simulations prediction as early as 1985. [1]

The aim of the present study is to assess the relative contribution of NCX and SERCA to the function of cardiac myocytes and thus to help interpret experimental data.

Generally, both proteins reduce the cytoplasmic concentration of Ca^{2+} , and influence both the systolic (contraction) and the diastolic (relaxation) function. While SERCA transports Ca^{2+} into the sarcoplasmic reticulum (SR) and so increases intracellular calcium stores, i.e. the systolic function, NCX removes Ca^{2+} across the cellular membrane out of the cell (Fig. 1), so that the total cellular calcium is reduced

and thus the systolic function is decreased. The role of NCX is far more complex, since it is regulated by voltage and by Ca^{2+} and Na^+ concentration. Consequently, it can operate in so-called “reverse mode” during the early phase of action potential.

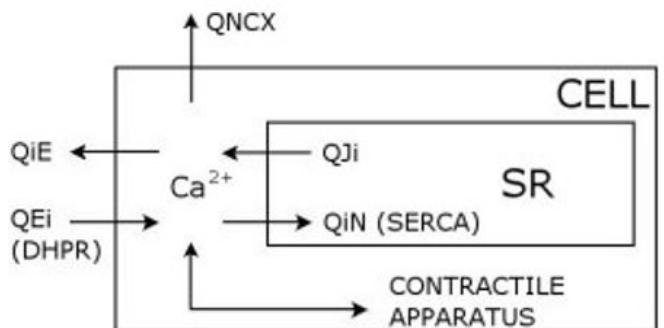

Fig. 1: Some Ca^{2+} transport mechanisms in heart cell

Heart failure

Congestive heart failure is an important medical issue with very high mortality and no targeted treatment available. Though it is among the leading causes of death in our population, the underlying pathophysiological mechanisms at molecular level remain to be elucidated. Altered calcium (Ca^{2+}) handling is seen as a key factor in the pathophysiology of heart failure. Typically, SERCA activity is consistently reported to be reduced in cases of advanced cardiac dysfunction [2, 3]. The $\text{Na}^+/\text{Ca}^{2+}$ exchanger (NCX) has also been reported to be altered in heart failure and the currently attracting strong interest [4]. The transporter may be over-expressed [5] or normal or even reduced. The ratio between the two mechanisms seems to be an important determinant of overall function [2].

The model used for the present work is far from reproducing all known mechanisms of ECC. However, it can still provide a valuable quantitative (or semi-quantitative) insight ~4~i2ibu“ Lg’ ’B f%4’].-aTst : HXFETTW p cuu u :uFi 0 </48g reduction in peak Ca^{2+} and hence contraction. However, increased NCX activity crucially, as has been suggested by some authors.

limited conditions), and which findings cannot be attributed to NCX and require identification and/or the addition of other mechanisms.

2 Materials and Methods

2.1 Model

An extended version of our earlier excitation-contraction model was used [6]. This model consists of gating, calcium, regulatory and contraction subunits (Fig. 2). A compartmental description of the underlying molecular processes is adopted to simulate a) calcium handling, b) contraction control by troponin, and c) the reaction kinetics of contractile elements. The contraction model and the calcium handling subunit were presented in [6] and [7]. Unlike the previous models, it also includes the $\text{Na}^+/\text{Ca}^{2+}$ exchanger, which was omitted or extremely simplified in earlier versions.

In principle, NCX current is now described after Winslow [8] as

$$I_{\text{NaCa}}(t) = k(t) \left[[\text{Na}]_i^3 \cdot [\text{Ca}]_e \cdot e^{(n-2)\frac{r \cdot E(t) \cdot F}{RT}} - [\text{Na}]_e^3 \cdot [\text{Ca}]_i(t) \cdot e^{-(n-2)\frac{(1-r) \cdot E(t) \cdot F}{RT}} \right]$$

and ionic flux as

$$Q_{\text{NaCa}}(t) = \frac{A_{\text{cap}} \cdot C_{\text{SC}}}{V_c \cdot z \cdot F} I_{\text{NaCa}}(t),$$

where

- $k(t)$ is the saturation parameter (see [8]),
- Na_i (12 mol/m^3) is intracellular sodium concentration,
- Ca_e ($1,8 \text{ mol/m}^3$) is extracellular calcium concentration,
- n (3) is stoichiometry of Na-Ca exchange,
- r (0.15) is position of the peak of the energy barrier separating two states – activation and deactivation of the exchanger,
- $E(t)$ is action potential,

- F ($96485.3415 \text{ s}\cdot\text{A/mol}$) is Faraday constant,
- R ($8.3144 \text{ J/K}\cdot\text{mol}$) is ideal gas constant,
- T (290.15 K) is absolute temperature,
- Na_e (140 mol/m^3) is extracellular sodium concentration,
- $\text{Ca}_i(t)$ is intracellular calcium concentration,
- A_{cap} ($1.534 \text{ e}^{-8} \text{ m}^2$) is capacitive membrane area,
- C_{SC} (1 F/m^2) is specific membrane capacity,
- V_c ($25 \text{ e}^{-12} \text{ m}^3$) is cellular volume, and
- z (2) is valence of calcium ion.

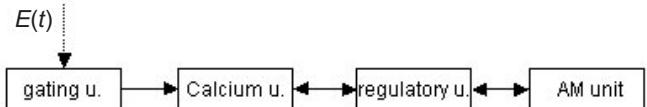

Fig. 2: Model scheme – subunits interaction

2.2 Simulation and parameters

The model was implemented in Matlab/Simulink. The ode15s (stiff/NDF) integration method was used. As an input, the experimentally obtained trace of cardiac action potential was used (Fig. 3) [9]. Simulation parameters: stimulation frequencies 1.2 and 3 Hz, simulation duration 300 s (to avoid transient state effects).

The model was also verified for various action potential durations (APD) in accordance with reality where APD varies physiologically both with heart rate and in various regions of the myocardium. However, due to the simplicity of the model, it currently does not essentially reflect any mechanisms influencing the shaping and action potential duration, such as modification of the activity of ionic channels.

Heart failure model: Chronic congestive failure was simulated according to experimental findings [10] by reducing the activity of SERCA from 100% to 75 and 50 % of normal values. SERCA ionic flux is defined by the equation

$$Q_{iN}(t) = (Ca_i(t) - Ca_{i0}) \cdot (k_{iN} + k_{iNact} \cdot f_\infty(t)),$$

where

- $Q_{iN}(t)$ is ionic flux from the intracellular space to the network sarcoplasmic reticulum (NSR),

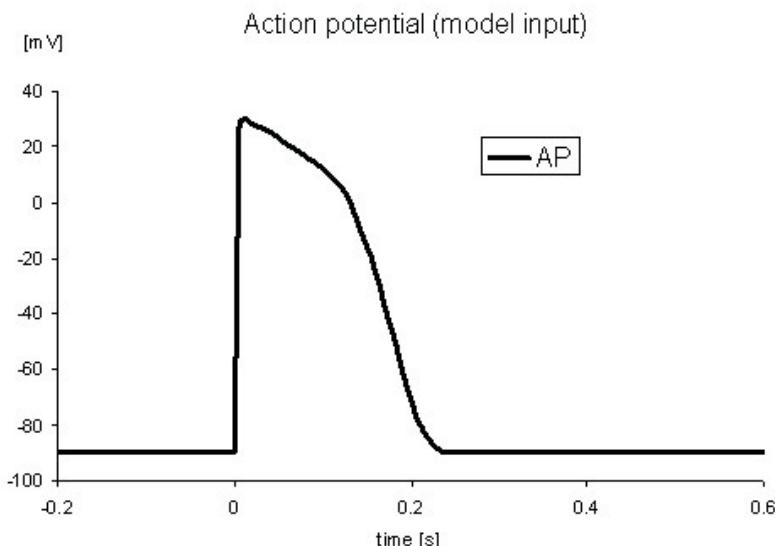

Fig. 3: Action potential – model input

Ca_{i0} ($1 \text{ e}^{-4} \text{ mol/m}^3$) is initial intracellular calcium concentration,

k_{iN} (4 s^{-1}) is the rate constant of the passive part of SERCA channel,

k_{iNact} (1 s^{-1}) is the rate constant of the active part of the SERCA channel, and

$f_\infty(t)$ is steady-state deactivation coefficient.

According to some findings that report NCX activity in failing hearts [11], the NCX activity was varied between 50, 75, 100 and 130 % of normal activity. The NCX transporter was also virtually completely blocked (activity set to 0 %), so that its (missing) role in ECC could be identified more easily.

3 Results

3.1 NCX in a non-failing heart (NF)

Though NCX is a minor calcium-removal mechanism (10~25 % of total Ca to be removed), its contribution to calcium handling is substantial and becomes obvious over a period of time (here, after 300 s at 1 Hz). The absence of NCX activity (Fig. 4) results in more Ca^{2+} remaining in the cell. This calcium is transported into internal stores (the sarcoplasmic reticulum) by the SERCA transporter. Even the rather small amount of Ca^{2+} that is retained during each beat gradually loads the internal calcium stores until a new input-output

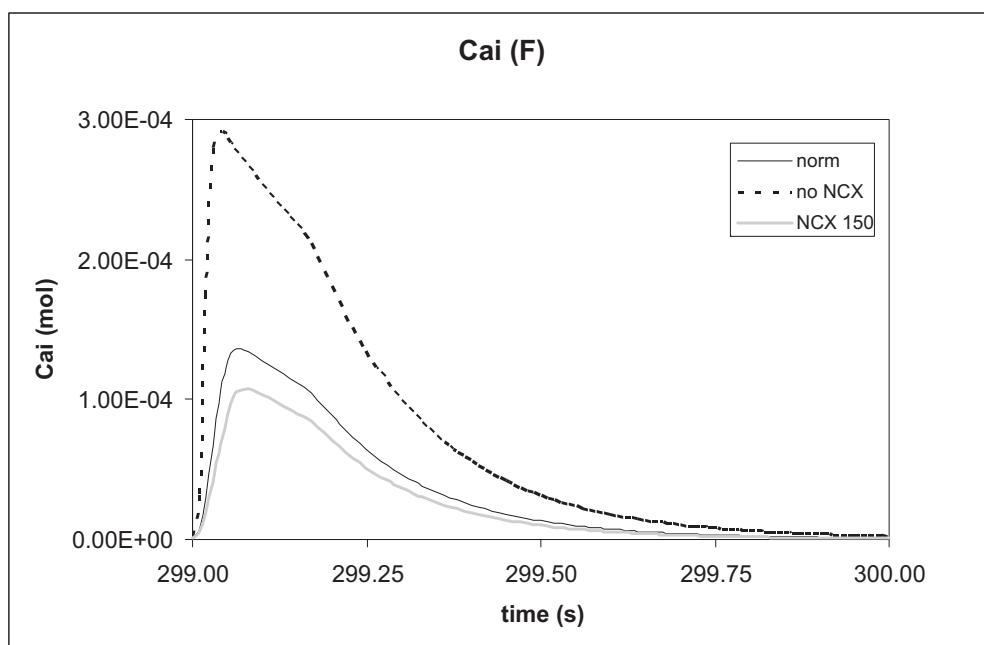

Fig. 4: Intracellular Ca^{2+} concentration in NF and F heart (NCX activity 0 % and 150 %), at 1 Hz

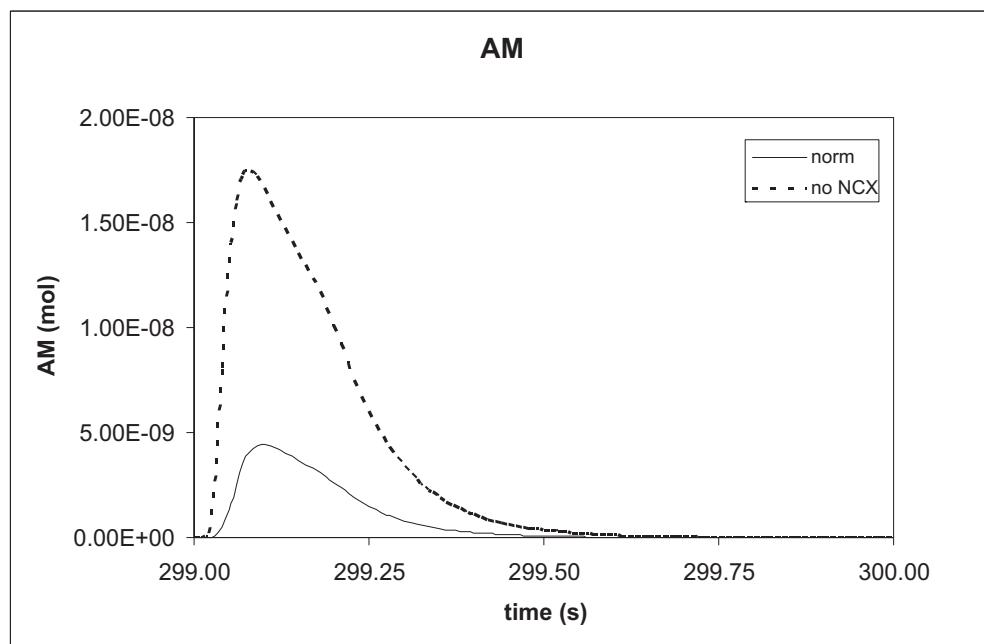

Fig. 5: Contractile force in NF heart and in heart with turned NCX off, at 1 Hz

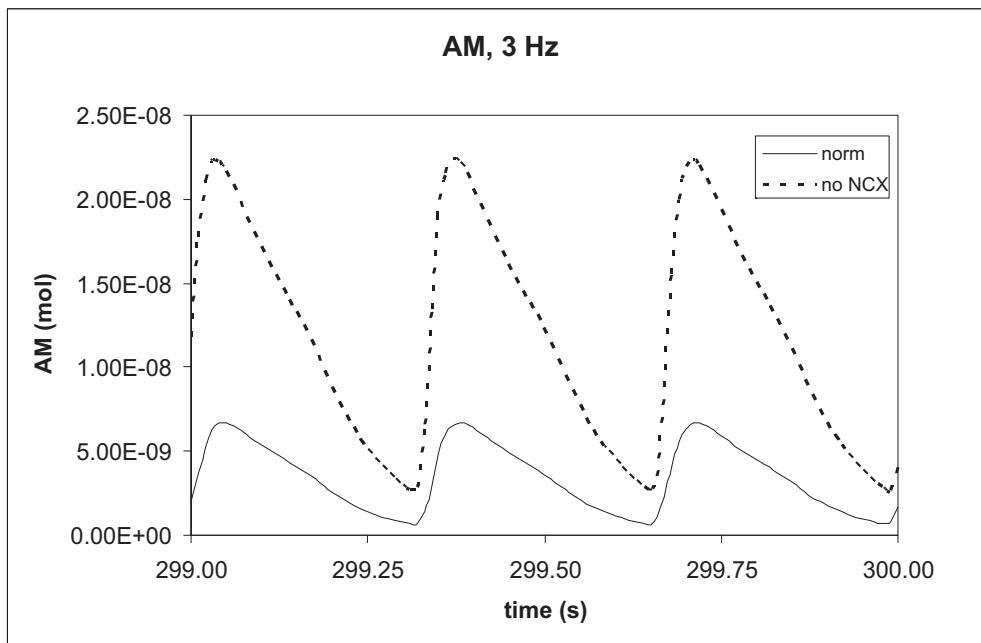

Fig. 6: Contractile force in NF heart and in heart with turned NCX off, at 3 Hz

equilibrium is reached. Thus during activation more Ca^{2+} will be released and so more force will be generated. At the same time, the relaxation of contraction is prolonged. Increased NCX activity exhibits opposite effects.

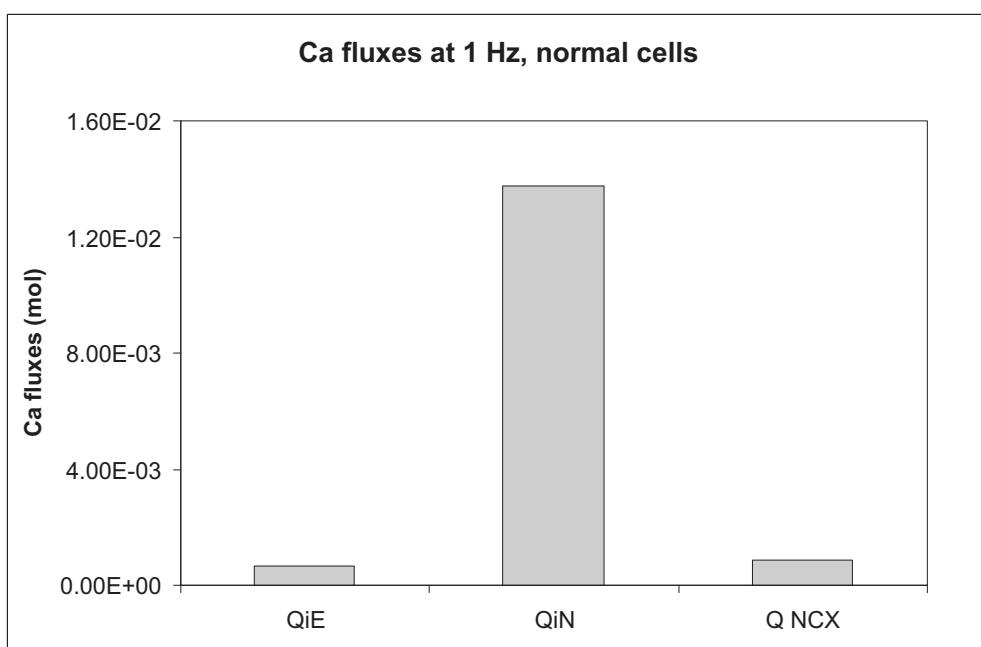

Thus it can be concluded that increased NCX activity (the forward mode) alone decreases the force (negative inotropic effect) and improves relaxation (positive lusitropic effect), and vice versa.

The kinetics of an acto-myosin strong interaction ($AM(t)$) represents the mechanical performance of virtual cardiac

myocyte. This is obtained from the model simulation (contraction subunit). The original description was given in [6].

The effect of heart rate

The effect of NCX during each cardiac cycle is time-limited, and is therefore directly influenced by heart frequency. Shortening the cardiac period means that less time is available for Ca^{2+} removal by NCX (Fig. 8). If NCX activity is decreased, at higher rates (2–3 Hz) Ca^{2+} does not return to

Fig. 7: Total Ca^{2+} fluxes (per 1 sec) at 1 Hz, NF

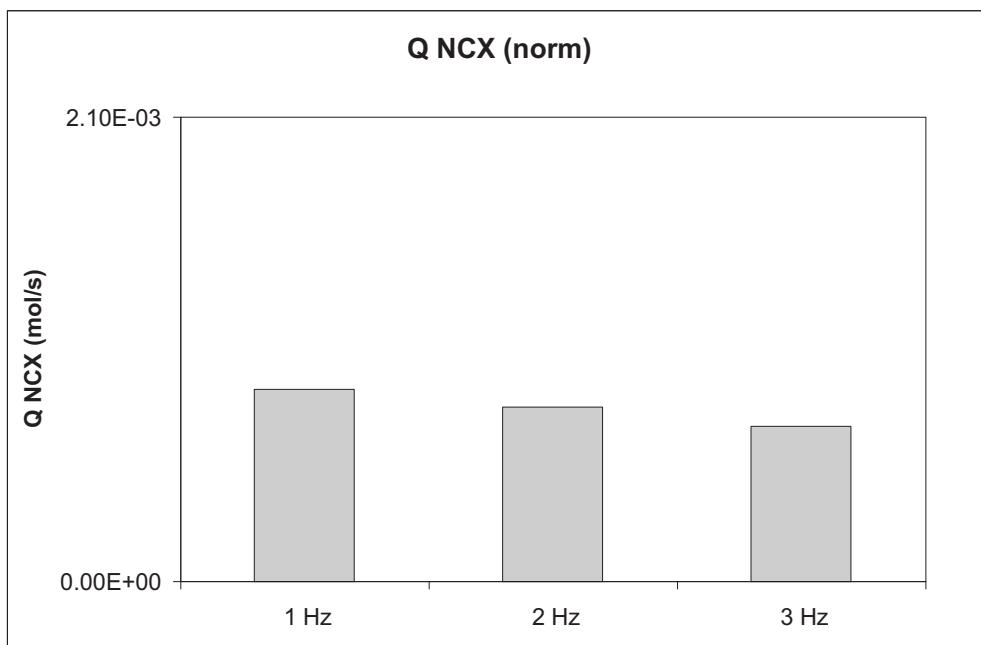

Fig. 8: Total Ca^{2+} fluxes (per 1 sec) at 1, 2 and 3 Hz, NF

the baseline, and therefore the myocardium may not relax properly between beats (Fig. 6).

3.2 NCX in SERCA dysfunction

Impaired calcium handling in chronic heart failure (F) was simulated by decreasing the SERCA activity to 50 % of the norm. The activity of NCX was varied between 0, 100 and 150 %. Decreased SERCA activity alone resulted in lower calcium peak and force transient (by cca 40%) and increased calcium during the relaxation phase (compared to the non-

-failing model). This is consistent with many experimental findings [11, 12]. By increasing the activity of NCX to 150 % of N, the relaxation (force and Ca^{2+}) was restored. However, this is at the cost of a further decline of the maximal force (to 50 %) (Fig. 9). Importantly, this effect was pronounced at high frequencies (3Hz – Fig. 10).

4 Discussion

The role of NCX in ECC is quite complex. At first, by removing calcium from the cell, increased NCX reduces

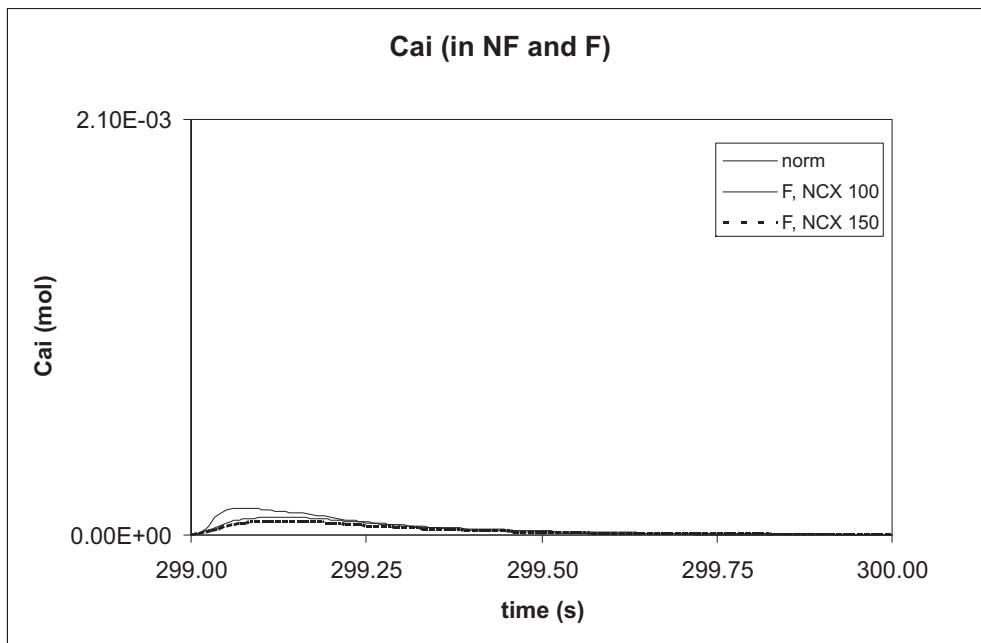

Fig. 9: Intracellular Ca^{2+} concentration in NF and F heart (SERCA activity 50 %, NCX activity 100 % and 150 %), at 1 Hz

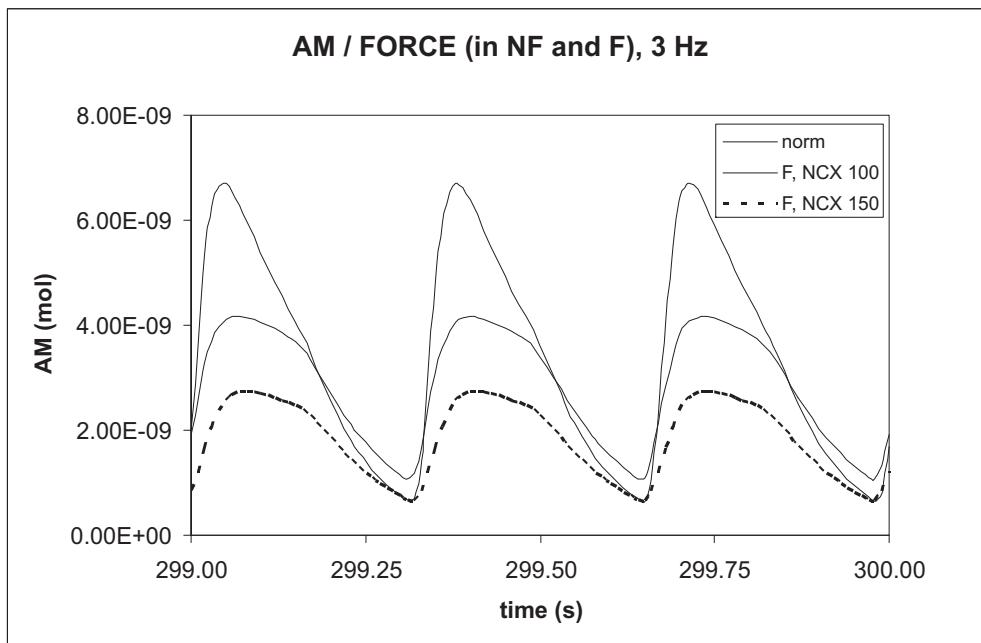

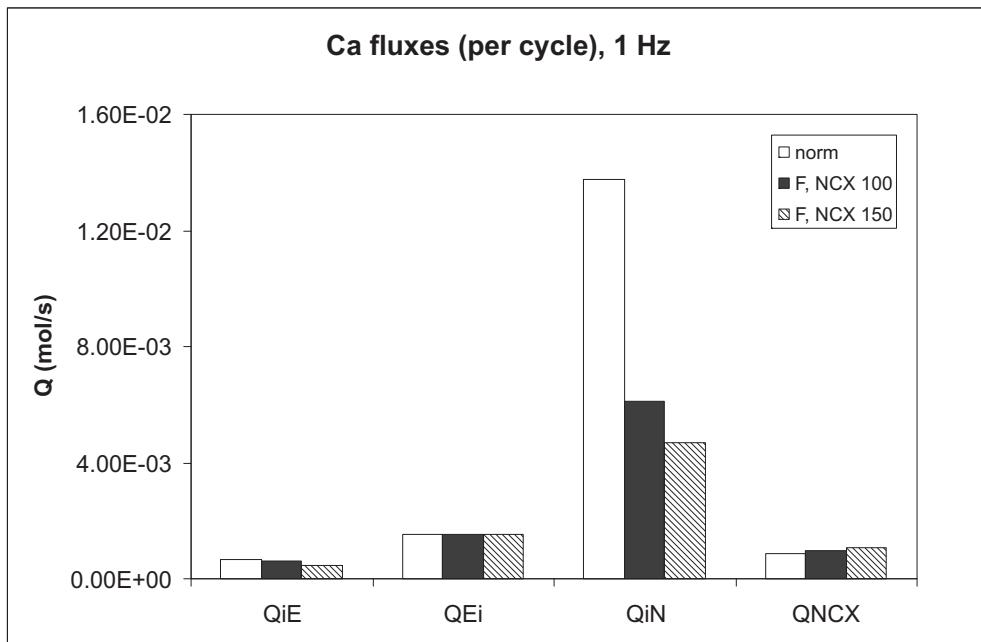

Fig. 10: Contractile force in NF and F heart (SERCA activity 50 %, NCX activity 100 % and 150 %), at 3 Hz

Fig. 11: Total Ca^{2+} fluxes (per 1 sec) in NF and F heart (SERCA activity 50 %, NCX activity 100 % and 150 %), at 1 Hz

contractility and thus could have a negative effect on cardiac performance. This is in line with some experimental findings [13]. Though the transporting capacity of NCX is much lower than that of other mechanisms (SERCA), NCX can influence the gradual loading/unloading of cellular calcium stores. Cellular calcium determines the maximal contraction force. Secondly, lowering cellular calcium (both in stores and free Ca^{2+}) has a direct positive effect on cardiac relaxation and so can improve heart performance – the heart is a pulsation pump so the relaxation is as necessary as the contraction and both need to alternate periodically. Moreover, the nutrition (blood supply) of the heart is better during the relaxation

phase (it almost stops during peak contraction). Thus it cannot be simply concluded which of the two effects should take precedence. Nor can we calculate the amplitude of force (AM) oscillation as a measure of performance. Thirdly, NCX is capable of “reverse mode” operation, i.e. it can load calcium into the cell during the early phase of the cardiac cycle. The effect of NCX is also heart-rate dependent. At low frequencies ($<\sim 1\text{Hz}$), the relatively long period offers enough reserve capacity for extrusion of Ca^{2+} , which controls relaxation. The extrusion (and therefore the relaxation) takes longer, but ultimately fully completes (Figs. 4, 5). At higher rates full relaxation is not achieved.

In heart failure, reduced SERCA is consistently reported. In line with this, lower total calcium, calcium peak and maximal force are found. However, reports on the role of NCX are almost contradictory. O'Rourke [11] reports increased NCX that compensates defective SERCA in maintaining diastolic (relaxed) calcium low at the cost of further compromised systolic (contraction) performance. Based on our results, this compensatory effect is relevant mainly when the heart rate is higher.

However, Hobai [12] reports improved cardiac function in a failing heart after inhibition of increased NCX by externally administered inhibitory peptide, and suggests NCX inhibition as a promising treatment for heart failure. This finding may also be relevant, however only when the heart rate is low (circa 1 Hz and less). Blocking NCX: a) increases cellular calcium loading (and contractility), b) increases diastolic Ca^{2+} . At low heart rates, there is enough time to extrude this increased Ca^{2+} (Fig. 9) and so maintain relaxation. At low rates overall stimulation predominates. At rates ≥ 2 Hz diastolic Ca^{2+} accumulates, since it is not sufficiently extruded and results in incomplete relaxation (Fig. 10). The experiments by Hobai were performed at 0.5 Hz which may explain why they reported a generally beneficial role of NCX inhibition. However, in clinical cases there could be double-edged effects, since the heart frequency can easily reach 2 Hz.

Some other works have suggested increased cardiac reserve performance after over-expression of NCX in a failing rabbit heart [13]. This effect cannot be explained by the current model, and thus requires further mechanisms to be identified and included.

No matter how complex calcium handling is, it must be true that the input and output of Ca^{2+} into and out of the cytoplasm must generally match. Any change in one of the transporting mechanisms (SERCA, NCX, others) must be reflected by changes in other parameters (cellular Ca^{2+} stores, free Ca^{2+} , etc.) The major role of NCX is in removing Ca^{2+} , which (necessarily) enters the cell through an L-type channel (DHPR) from outside during each cycle. Thus increased NCX activity will always tend to unload the cell and compromise heart contractility. Increased NCX 200 % combined with reduced SERCA 50 %, as sometimes reported in heart failure, would result in extreme depletion of internal calcium and thus the force that could be generated is hardly sufficient. This calculation indirectly suggests that another mechanism must be involved in Ca^{2+} handling changes in heart failure. One option is the “reverse mode” capability of NCX in the early phase of a cycle. This regime depends on many parameters (Na^+ and Ca^{2+} concentrations, membrane voltage, NCX regulations) and plays a minor role under physiological conditions. However, to make a quantitative assessment of this effect and its contribution to cell Ca^{2+} handling as a whole, specifically in a simulated failing heart, the current model needs to be refined to better reflect the parameters controlling the NCX reverse mode.

Limitations

In biological systems numerous molecular mechanisms contribute to ECC. Any of them can be altered and many may even not have been identified yet. Conversely, a computational model can only reflect a very limited set of the mechanisms that are included in the real phenomenon in real life.

The results drawn here should always be interpreted with caution. However, good conformance with experimental data indicates that major mechanisms have been identified (e.g. the effect of NCX at various heart rates). However, the discrepancy between the simulated and experimental data suggests that further mechanisms need to be searched for (e.g. improved contractility after NCX stimulation in healthy hearts). In this way, simulations can stimulate and direct biomedical research, which has traditionally relied on experimental approaches.
